Abstract

The electronic structure of Fe has been experimentally studied using angle-resolved photoemission spectroscopy (ARPES) since the early days of photoemission. Yet, the existence and nature of the Fe(001) surface state remain a subject of ongoing debate. Fe(001) is considered a prototypical transition metal system and moreover, one of the key players in the spintronics research. Here, we present the electronic structure of Fe(001) epitaxially grown on Au(001), mapped by high-resolution ARPES within the entire surface Brillouin zone, to demonstrate for the first time the exact location and extent of the Fe(001) surface state. The experimental results are supported by the relativistic slab calculations performed using density functional theory (DFT). The surface state observed for the pristine Fe(001) surface vanishes after overnight rest of the sample in ultrahigh vacuum as well as after intentional exposure to 5 Langmuir of oxygen which proves that it is not topologically protected. Furthermore, the dispersion of the surface state is found to depend on the relative orientation of the magnetization, which is explained based on the DFT results as related to the Rashba effect. These new experimental and theoretical results contribute to the existing knowledge on the electronic properties of Fe(001) with relevance for the basic research as well as for spintronic effects, such as tunneling anisotropic magnetoresistance.

1. Introduction

The surface electronic states, which occur due to breaking of the translational symmetry along the surface normal, exist for example at the surfaces of noble metals: Au(111), Ag(111) and Cu(111), where they form well-defined *sp*-like parabolic states centered around the $\bar{\Gamma}$ point [1].

The surfaces of transition metals are also known to host surface states formed by dangling *d* bonds [2, 3], but also *sp*-like states are observed as in the case of Ni(111) [4]. The surface states and surface resonances have been theoretically described and experimentally observed for Fe(110) surface [5–10], also in the form of Fermi arcs [11], related to the postulated topologically nontrivial nature of Fe [12, 13].

The surface states of Fe(001) are particularly important due to their technological relevance, as the interfacial resonance states in the Fe/MgO/Fe magnetic tunnel junction [14] are inherited from the surface states of clean Fe(001) [15, 16]. Moreover, the dependence of the Fe(001) surface state on the magnetization direction due to spin-orbit coupling has been recognized as a source of the tunneling anisotropic magnetoresistance, which allows the spin-dependent tunneling in devices with single Fe(001) electrode [17].

Also, the electric-field induced change of the minority surface state of Fe(001) was found theoretically to be responsible for the electric-field modification of magnetic anisotropy in ultrathin Fe(001) films [18]. In addition, the spin–orbit effects in Fe thin films are also relevant for the closely related system of oxygen-passivated Fe(001)-p(1 × 1)O surface, which is nowadays routinely used in spin-detectors that rely on both exchange and spin–orbit spin-dependent electron scattering [19].

The surface states of Fe(001) have been studied experimentally even before their role in spintronics was revealed. Due to technical limitations, previous experimental works focused on the identification of the surface state only in the very center of the surface Brillouin zone (SBZ) [2, 20–22] or along the $\bar{\Gamma} - \bar{X}$ line [16, 23]. Already in 1983, the surface electronic structure of Fe(001) has been investigated using synchrotron-based angle-resolved photoemission spectroscopy (ARPES) by Turner and Erskine [23] and the two surface states, lying within the projected band gap of the bulk electronic states, have been identified. By comparison to the early slab calculations, one of these states, lying directly below the Fermi level (also at the very $\bar{\Gamma}$ point) has been identified as the minority-spin state, while the other, located approximately at the binding energy of 2 eV, has been identified as its majority-spin counterpart. In the following years, the Fe(001) surface state in the center of the surface Brillouin zone ($\bar{\Gamma}$ point) lying directly below the Fermi level has been claimed by Vescovo *et al* to be of the majority-spin character [20]. On the other hand, Stroscio *et al* have shown using scanning tunneling spectroscopy the existence of the unoccupied surface state along the surface normal, which was interpreted as minority-spin by comparison with the slab calculations [2]. This interpretation was later verified experimentally by spin-polarized photoemission on the potassium covered Fe(001) [21] and by spin-polarized inverse photoemission [22]. In 2009, Plucinski *et al* have shown spin- and angle-resolved spectra for Fe(001) films grown on W(001), along the entire $\bar{\Gamma} - \bar{X}$ line and demonstrated the existence of the occupied minority surface state along most of the $\bar{\Gamma} - \bar{X}$ distance, which however disappears at both $\bar{\Gamma}$ and $\bar{X}$ [16]. In recent years some of us have extensively studied the electronic structure of Fe(001) films grown on Au(001) [24–27] and found no signatures of the surface states in the experimental band structures measured both using lab-based high-resolution ARPES with $E_{h\nu} = 16.8$ eV [24] as well as in the k-space microscopy studies performed using $E_{h\nu} = 70$ eV [25–27].

Here, we present experimental results that demonstrate the existence of the Fe(001) surface state for Fe films grown on Au(001), using the same recipe as for the samples discussed in [24–27], but prepared in another deposition system. We suspect that the presence of this surface state is extremely sensitive to the adsorption of the residual gases, which are inherently present in ultrahigh vacuum chambers. We demonstrate by ARPES and relativistic slab calculations the minority surface state of Fe(001) of a four petal-flower shape at the Fermi level, with the petals aligned with $\bar{\Gamma} - \bar{X}$ and disappearing near $\bar{\Gamma}$, as theoretically predicted by Chantis *et al* [15, 17, 28]. The photon energy dependence, significant energy broadening as well as lack of full symmetry with respect to the border of the SBZ point to the surface resonant character of the observed surface state at least close to the $\bar{X}$ points, which is in accord with the theoretical predictions of the weak mixing of this state with the bulk bands [17]. We show that the surface state in the immediate vicinity of the $\bar{X}$ points exhibits strongly asymmetric dispersions that can be explained by the Rashba-type effect. Our findings support the importance of the spin–orbit coupling for the electronic structure of materials even as light as Fe.

2. Experimental and theoretical methods

The entire experiment was performed in the Phelix end-station at the SOLARIS National Synchrotron Radiation Center in Kraków [29]. Fe films were grown in the Phelix preparation chamber. Au(001) crystal was cleaned by cycles of Ar sputtering and annealing at $T = 800$ K for 10 min until a c(28 × 48) surface reconstruction characteristic for a clean Au(001) crystal [30] was clearly visible in low energy electron diffraction (LEED) (supplementary figure S1(a)). Fe films were deposited on such prepared Au(001) single crystal at low temperature ($T = 100$ K) using molecular beam epitaxy and gently annealed up to 800 K. This preparation procedure was found previously to result in high quality Fe(001) films, with no Au present on the Fe surface [24]. In the currently reported experiments we have also used x-ray photoelectron spectroscopy (XPS) to verify cleanliness of the pristine Fe(001) surface (supplementary figure S2). Fe(001) grows on Au(001) following the epitaxial relationship: bcc Fe[100] || fcc Au[110], which was verified using LEED (supplementary figure S1(b)). The minute in-plane lattice mismatch between Fe(001) and Au(001) which equals to 0.6%, promotes high-quality epitaxial growth, which is proven by very sharp Fe(001) LEED spots with negligible background (supplementary figure S1(b)). The major experimental studies, including oxygen adsorption experiment were done on films with a thickness of approximately 80 monolayers (ML). A thinner film (40 ML-thick) was grown for comparison and monitored after overnight rest in ultrahigh vacuum (UHV) conditions. Both film thicknesses showed qualitatively the same picture of the Fe(001) surface state. The samples were remanently magnetized *in situ* using a permanent magnet, mounted on the

PTS-type sample holder, directly after growth. A photograph of the used setup is included in supplementary figure S1(c). The magnetic field generated by the permanent magnet (approximately 140 mT) is much more than the coercivity of a thin Fe film grown on Au(001), being typically of the order of 1 mT [31]. The samples were magnetized along Fe[100] direction, which is an easy axis dictated by the magnetocrystalline anisotropy of Fe(001). The Curie temperature of the studied Fe films is well above the room temperature [32]. Photoemission experiments were performed at the Phelix beamline using angle-resolved electron energy analyzer from SPECS which operates with scanning lenses system that facilitate mapping of the electronic dispersions. In order to map the entire SBZ of Fe(001) it was necessary to employ in addition change of the polar and azimuthal angles. Specifically, to access $\bar{X}$ points that differ due to symmetry breaking by the in-plane magnetization, we changed the azimuthal angle. For the measurements around the $\bar{\Gamma}$ ($\bar{X}$) point, the synchrotron light reaches the sample at the angle of 54.7° (39.7°) with respect to sample normal. A six-axis manipulator was cooled with liquid helium during ARPES measurements. Most of the measurements were performed using photon energy of $h\nu = 70$ eV and *s*- or *p*- polarized light. The oxygen adsorption experiment was performed using high purity oxygen gas dosed by a leak valve in the preparation chamber to the total dose of 5 Langmuir (L). Such a dose is expected to lead to the oxygen coverage close to a ML and is still well below the exposure that would result in a surface oxide layer. The chemical state of Fe after oxygen adsorption was monitored using XPS and the amount of the adsorbed oxygen was estimated to be equal to 1 ML (supplementary figure S2). In addition, constant energy maps were acquired using a range of photon energies, between 55 eV and 125 eV and *p*-polarized light.

First-principles calculations were carried out within the all-electron full-potential linearized augmented-plane-wave formalism with the FLEUR [33] code. For the bulk calculations, performed within generalized gradient approximation (GGA) [34], we used an angular momentum cutoff of $l_{\max} = 8$ in the atomic spheres and a plane-wave cutoff of 5.0 bohr^{-1} in the interstitial region. We used an experimental bcc Fe lattice parameter of $2.87 \text{ \AA}$. The 3s and 3p orbitals were treated as semicore by the use of local orbitals. We used a $10 \times 10 \times 10$ **k**-point sampling of the Brillouin zone.

To study Fe(001) surface states, the GGA slab calculation was performed using a 27 layer film with an angular momentum cutoff of $l_{\max} = 8$, a plane-wave cutoff of 3.8 bohr^{-1} and $12 \times 12 \times 1$ **k** points. For the in-plane lattice constant, a theoretical GGA value of bulk Fe was used, i.e. $2.83 \text{ \AA}$, which allowed for correct relaxation of the thin film interlayer spacings that was found to be equal to $d_{12} = -0.65\%$, $d_{23} = +3.95\%$, $d_{34} = 1.33\%$, and $d_{45} = 0.05\%$. Determination of the localization of electronic states within the surface region was performed according to the contribution within the atomic spheres in the upper two layers.

To simulate the photoemission spectrum based on the bulk initial band structure, we use the same scheme as described in detail in reference [26]. In short, we take into account the experimental energy broadening ($\Delta E = 20 \text{ meV}$) as well as the broadening in the perpendicular wavevector ($\Delta k_{\perp} = 0.33 \text{ \AA}^{-1}$) related to the escape depth of the photoexcited electron via the Heisenberg principle. The value of $\Delta k_{\perp}$ was found by adjusting the simulation result to the experimental data.

To obtain the photoemission intensity, we integrate the initial state spectral function in $k_{\perp}$: [35, 36]

$$I(E^f, E^i) \propto \int_{-\infty}^{\infty} dk_{\perp} |T^f|^2 |M_{fi}(k_{\perp})|^2 \cdot \frac{\Delta k_{\perp}}{(k_{\perp} - k_{\perp}^0)^2 + (\Delta k_{\perp}/2)^2} \cdot \frac{\Delta E}{(E^i - E^i(k_{\perp}^0))^2 + (\Delta E/2)^2} \quad (1)$$

$E^i(k_{\perp}^0)$ is an input to the simulation given by the result of the GGA *ab initio* calculation of the bulk electronic structure. In our simulations, we assume the final state surface transmission (T^f) and photoexcitation matrix elements (M_{fi}) to be equal to unity. The value of $k_{\perp}^0$ is determined using the free electron final state model with the inner potential $V_0 = 11 \text{ eV}$, where E_{kin} is the kinetic energy of the photoexcited electrons, while Θ is the emission angle:

$$k_{\perp}^0 = \sqrt{(2m/\hbar^2)(E_{\text{kin}} \cos^2 \theta + V_0)}. \quad (2)$$

3. Experimental and theoretical results

3.1. Electronic band structure along the $\bar{\Gamma}$ – $\bar{X}$ direction

To facilitate orientation in the reciprocal space, a sketch of the bulk Brillouin zone (BBZ) of bcc Fe and a SBZ of Fe(001) is shown in figure 1(a). The Fe $\langle 100 \rangle$ directions correspond to the Γ –H (Δ) directions in the reciprocal space. Γ –H (Δ) directions project to the (001) surface as a $\bar{\Gamma}$ – $\bar{X}$ direction within the SBZ. The

colored surface represents values of the $k_{\perp}^0$ wavevectors accessed in our photoemission experiment. The electronic band structure measured for a pristine Fe(001)/Au(001) surface using $E_{h\nu} = 70$ eV and s -polarized light along the $\bar{\Gamma}$ – $\bar{X}$ line is presented in figure 1(b). The results obtained for p -polarized light are presented in the supplementary information, figure S3. The photoemission spectrum measured after oxygen adsorption is presented in figure 1(c). An experiment of oxygen adsorption is a well-established procedure to distinguish the surface states from the bulk states [5, 16, 20, 22, 23]. Both spectra, before and after oxygen adsorption, can be compared to the bare GGA bulk bands along the $\bar{\Gamma}$ – $\bar{H}$ (Δ) line, which are shown as an overlay in figure 1(c), where the blue/red color shows the predominantly minority/majority spin character of the bulk bands. The experimentally observed broadening of the electronic states in the Fermi level region is caused mostly by the spread of the allowed $k_{\perp}$ vectors that results from the uncertainty principle [26]. The photoemission simulation performed within the scheme described in reference [26] that involves the $k_{\perp}$ broadening, based on the bulk bcc Fe band structure as given by the GGA is presented in figure 1(f). It is important to note that the spectrum of clean Fe(001) (figure 1(b)) shows high spectral weight between the minority Δ_5 band and the Fermi level, where there are no bulk states expected close to the Fermi level, for k_y wavevectors between approximately 0.5 and $0.8 \text{ \AA}^{-1}$ and for the projection of $k_{\perp}$ close to the bulk $\bar{\Gamma}$ point, (figure 1(f)). On the other hand, the photoemission spectrum measured after oxygen adsorption (figure 1(c)) shows much smaller spectral intensity in the same region, which points to the surface character of the state observed for a pristine surface. In the same time, such strong damping of the surface state by oxygen adsorption indicates that the state is topologically trivial.

In addition, we present results of the GGA-based slab calculations of the surface electronic structure of Fe(001) along the $\bar{\Gamma}$ – $\bar{X}$ line (figure 1(e)). Here, the size of the symbol corresponds to the localization of the state in the surface region, while the blue/red colors mark predominantly minority/majority states. Clearly, the minority surface state is expected by theory along this k -space direction, right below the Fermi level, dispersing slightly towards deeper binding energies for larger k values. It consists of a combination of d_{xz} and d_{yz} orbitals and is well-recognized in the literature thanks to the earlier theoretical studies [2, 16, 37]. The spectrum of a clean Fe(001) surface (figure 1(b)) shows also an intense parabolic-like state that passes the Fermi level close to the $\bar{X}$ point. This parabolic-like state survives the oxygen adsorption, therefore we

interpret it as a bulk majority Δ_1 state, even though its energetic position and dispersion is similar to the theoretically predicted majority surface state (figure 1(e)). In addition, energy distribution curves (EDC) derived from the measured 2D spectra for $k_y = 0.6 \text{ \AA}^{-1}$, are presented in figure 1(d). Clearly, the surface state observed for the pristine surface (full symbols) is quenched after oxygen adsorption (open symbols). The considerable energy spread of the observed surface state, which is close to 100 meV, can be partially attributed to the scattering-related lifetime effects, which are significant in Fe, even in the minority-spin channel [38]. On the other hand, the theoretical considerations of Chantis *et al* [17] on the nature of the four-petal Fe(001) minority surface state include broadenings of this state due to coupling with both minority and majority spin bulk bands. Spin-flip scattering that govern tunneling magnetoresistance is theoretically expected to depend strongly on this intrinsic width of the resonant surface states [39].

3.2. Fermi surface in the vicinity of the $\bar{\Gamma}$ point

In this section we will discuss the electronic band structure in the center of the SBZ of a pristine Fe(001) surface (figure 2(a)), in comparison to the oxygen-adsorbed Fe(001) (figure 2(b)). The result of the GGA-based slab calculation is presented in figure 2(c), while the result of the bulk GGA calculation is shown in figure 2(d) (the method used here is the same as in figure 1(e)). The electronic state visible in the vicinity of the $\bar{\Gamma}$ point for clean Fe(001) surface within the (k_x, k_y) plane slightly deviates from four-fold symmetric, with some intensity difference visible between the negative and positive k_x values related to the symmetry breaking by the light incidence direction (the synchrotron light is coming from the right of the image). The intensity at the very $\bar{\Gamma}$ point is much smaller than in the surrounding region. Such a picture could be in principle consistent with the bulk electronic structure predicted by the GGA *ab initio* calculations (figure 2(d)), as well as with the surface state predicted by the slab calculation (figure 2(c)), although the four-fold symmetric bulk state is expected at larger binding energies (below $E_b = 0.2 \text{ eV}$). The feature that helps to distinguish the two is the dispersion of the state observed close to the $k_x = 0.6 \text{ \AA}^{-1}$ line. The experiment for a pristine Fe(001) surface shows the electron-like dispersion of this state, exactly as the one predicted by the slab calculation for the surface state (figure 2(c)), in contrast to the hole-like (dispersing 'downwards') bulk state (figure 2(d)). The spectra observed after oxygen adsorption (figure 2(b)) support this picture. Apparently, the four-petal-like state that was spreading from the vicinity of the $\bar{\Gamma}$ point towards

the $\bar{X}$ point and was clearly visible at $k_x = 0.6 \text{ \AA}^{-1}$ got suppressed by the oxygen adsorption. The state that survived the adsorption is the theoretically predicted bulk state.

The results of the complementary measurements performed using p -polarized light, as well as additional cuts along $k_x = -0.6 \text{ \AA}^{-1}$ lines are presented in the supplementary materials, figure S4.

3.3. Fermi surface in the vicinity of the $\bar{X}$ point. Rashba effect

Figure 3 presents the experimental data collected in the vicinity of two $\bar{X}$ points using p -polarized light for a pristine and oxygen-covered Fe(001) surface. The two $\bar{X}$ points are distinguished due to their positions with respect to the magnetization direction. The $\bar{X}_1$ ($\bar{X}_2$) point lies on the $\bar{\Gamma}$ - $\bar{X}$ line perpendicular (parallel) to the magnetization direction as shown on the sketch of the SBZ in figure 3(a). The symmetry of the thin film under investigation is lowered with respect to the symmetry of the bulk crystal by the presence of the sample surface which breaks the translational symmetry and also by the magnetization vector which lies in the sample plane. As a result, the only symmetry operation that is left is a single mirror plane which is perpendicular both to the sample surface and to the in-plane magnetization (the $\bar{\Gamma}$ - $\bar{X}_1$ line lies within that mirror plane). Consequently, the electronic band structure that we observe around the $\bar{X}_1$ point is symmetric with respect to the $\bar{\Gamma}$ - $\bar{X}_1$ line, both for the pristine surface, which shows the surface state (figure 3(a)) and for the oxygen-covered surface (figure 3(b)). We observe also in this region of the SBZ that the surface state disappears after oxygen adsorption (figures 3(a) and (b)). In addition, after oxygen adsorption we observe apparent sharpening of the features at the Fermi surface that we mark with $\alpha-$ and $\alpha+$ labels, in analogy to the terminology used in [24]. According to [40], this effect can be attributed to the narrowing of the d-bands as a result of enhanced electron-electron correlations caused by the oxygen adsorption. Additional momentum-distributions curves derived from the discussed constant energy maps are presented in the supplementary information, figure S5.

Breaking of the symmetry by the presence of the sample surface and in-plane remanent magnetization is manifested by the asymmetrical electronic band structure. More specifically, for the oxygen-covered surface (figure 3(d)) we observe that $\alpha-$ and $\alpha+$ features are not the same (as it is in the case of the $\bar{X}_1$ point). The $\alpha+$ feature is clearly shifted from the $\bar{X}_2$ point (marked by a red dot), which is a manifestation of the opening of the spin-orbit gap. This effect was observed previously by some of us in the same sample system for

100 ML Fe films [24]. Opening of the spin–orbit gap near the $\bar{X}$ point is predicted by the bulk calculation of the electronic band structure, however the bulk consideration does not capture the lowered symmetry observed for a thin film [24]. Interestingly, in the experiment that we are reporting here, we had access also to the pristine Fe(001) surface, and we can analyze the position/location of a surface state with respect to the bulk states for such an asymmetric case. Figure 3(c) shows clearly that the intense state at the Fermi level is visible only for the positive k_x values (marked by yellow arrows in figure 3(c)), and is located exactly within the asymmetric spin–orbit gap of the bulk states (figure 3(d)).

Now we will compare the experimentally observed asymmetric surface state with the prediction of the *ab initio* calculation of the surface electronic structure. This is presented in figure 4. Here, again the size of the symbol corresponds to the localization of the state in the surface layer, and blue color indicates the minority spin character. The cut through the band structure is performed at $k_x(y) = 1.2 \text{ \AA}^{-1}$ along the wavevector perpendicular (figure 4(a)) and parallel (figure 4(b)) to the magnetization direction. Clearly, the minority surface state is asymmetric for the former case, and symmetric for the latter. The two branches of the surface state are shifted on the energy scale for the asymmetric case and the separation between them reaches $\Delta E = 64 \text{ meV}$. In the GGA result, the surface state is located above the theoretical Fermi level for these $E_{x(y)}$ cuts, while in the experiment its lower branch is occupied (figure 4(c)).

The asymmetry with respect to $\mathbf{k}$ observed both in the experiment and in the calculation can be explained as a Rashba-type interaction [41]. Rashba effect occurs upon inversion symmetry breaking e.g. at the surface. The surface potential gradient affects the Bloch wavefunctions of the conduction electrons such that they experience a momentum-dependent effective magnetic field leading to spin-momentum locking. In the case where spin–orbit coupling coexists with exchange interaction, a single-particle energy can be defined by the formula introduced in reference [42]. If the magnetization is aligned antiparallel to the *y*-axis, this reads:

$$\epsilon_{\mathbf{k}\sigma} = \frac{\hbar^2}{2m} \left[(k_x + \sigma k_0)^2 + k_y^2 \right] - E_R - \sigma \left[(J_0 S)^2 + (\alpha_R k_y)^2 \right]^{1/2}, \quad (3)$$

where σ is the spin quantum number $\sigma = \pm 1$, α_R is the Rashba parameter, k_0 is the momentum shift ($k_0 \propto \alpha_R$), E_R is the energy shift ($E_R \propto \alpha_R^2$) and $J_0 S$ represents exchange splitting. According to equation (3), the band shift is expected for the in-plane wavevectors perpendicular to the magnetization direction, which

is exactly what is observed in the experiment (figure 3(c)). Chantis *et al* have theoretically predicted such Rashba effect for the studied here four-petal minority surface state of Fe(001), however in the other part of the SBZ, namely closer to the $\bar{\Gamma}$ point [17].

For nonmagnetic materials, where the Rashba effect is most commonly observed, it leads to the splitting of a spin-degenerate electronic band into two spin-polarized branches. The size of the Rashba effect (α_R) depends on the strength of the electric field in the surface region and on the size of the intra-atomic spin-orbit coupling. A typical example of the Rashba-effect is spin-splitting of a heavy metal Au(111) surface state. In reference [43], the influence of the intra-atomic spin-orbit coupling on the Rashba splitting has been analyzed by comparison of the interface states in $p(1 \times 1)\text{O}/\text{Lu}(0001)$ ($Z = 71$) and $p(1 \times 1)\text{O}/\text{Y}(0001)$ ($Z = 39$). The Rashba splitting has been observed in the former case and absent in the latter. The observation of the Rashba effect has also been reported for the magnetically-ordered materials, where the spin direction is governed by the exchange interaction [43–45]. Examples of magnetic systems where the Rashba effect was observed include: $\text{Gd}(0001)$ and $p(1 \times 1)\text{O}/\text{Gd}(0001)$ [44], $\text{Tb}(0001)$ [43] and quantum wells of $\text{Co}/\text{W}(110)$ [45]. On the other hand, the effect was found to be not-observable in $\text{Co}/\text{Mo}(110)$, which was attributed to the weaker spin-orbit coupling of Mo with respect to W [45]. In the earlier work of some of us [24], the asymmetric spin-orbit gap of the bulk states measured for the $\text{Fe}(001)/\text{Au}(001)$ was also interpreted as a Rashba-type effect. Here, we have shown for the first time experimentally such Rashba-type asymmetry for the surface states of an element as light as Fe, proving the relevance of spin-orbit coupling in this material.

We have performed ARPES experiments on a couple of pristine $\text{Fe}(001)/\text{Au}(001)$ films, each time obtaining similar results. Particularly interesting are photoemission spectra recorded for a thinner film, of approximately 40 ML, as they reveal clear quantum well states formed by the bulk bands in the vicinity of the $\bar{M}$ point. The results obtained for that sample are presented in figures 4(e) and 5. In figure 4(e) we present an illustration created by combining multiple measurements taken in different regions of the SBZ with 70 eV photons and p -polarized light. The part of the SBZ in the vicinity of the $\bar{M}$ point was measured for one of the $\bar{M}$ points and symmetrized. The electronic states close to each of the $\bar{X}$ points were measured separately by rotating the sample along normal. This illustration nicely captures the four petal-like shape of the $\text{Fe}(001)$ surface state and asymmetry near the $\bar{X}_2$ and $\bar{X}_4$ points. The green dashed line in the figure marks the mirror plane perpendicular to the magnetization direction, which is valid when we neglect the light incidence direction (the light is coming from the bottom in the central part of the illustration). In figure 5 we are presenting constant energy cuts near $\bar{X}_1$ and $\bar{X}_4$ points together with selected $E(k)$ cuts, taken in the range $k_{x(y)} = 0.95 - 1.2 \text{ \AA}^{-1}$ for a 40 ML Fe film. Figures 5(a) and (b) contain results for a pristine $\text{Fe}(001)$ surface. Clearly, the surface state (marked with yellow arrows), appears symmetric (figure 5(a)) or asymmetric (figure 5(b)) depending on the magnetization direction. The $\text{Fe}(001)$ surface state is sensitive to the adsorption of the residual gases of the UHV chamber, as it disappears after overnight rest of the sample in the UHV conditions (figure 5(c)).

In figure 5 one can observe that $E(k_x)$ cuts are not symmetric with respect to the SBZ border ($k_{x(y)} = 1.1 \text{ \AA}^{-1}$), which would be expected for pure surface states. The clear symmetrical behavior is observed only for the short range of k_y values directly near the $\bar{X}_4$ point (figure 5(c), $k_y = 1.05, 1.1, 1.15 \text{ \AA}^{-1}$, spectra surrounded by the yellow box). We can compare this experimental result to $E(k_x)$ cuts near the SBZ border, as calculated by density functional theory (DFT) (GGA). Such results are presented in figure 6. We see, that the previously identified asymmetric minority surface state (blue) which lies directly above the GGA Fermi level extends towards the occupied part of the band structure exactly at the border of the Brillouin zone ($k_y = 1.1 \text{ \AA}^{-1}$). Also, in the close vicinity of the SBZ border, this state has no or very little overlap with the quantum well states formed by the majority bulk states (band structures surrounded by the orange box). On the other hand, moving away from the SBZ border, we observe a clear overlap between the minority surface state and the majority bulk bands, which strongly suggests that this state turns into a surface resonance with the change in k_y , in accord with the previous theoretical predictions [39]. Moreover, we have performed photon energy dependent measurements in the vicinity of the $\bar{X}$ point, using a range of photon energies between 55 eV and 125 eV, which are presented in the supplementary information, figure S6. We see that the observed states, including those located along the $\bar{\Gamma}$ – $\bar{X}$ line up to at least $k_x = 0.6 \text{ \AA}^{-1}$ are visible only within a short range of photon energies (65–80 eV) indicating bulk-like character of surface resonances. We also note, that the clearly asymmetric surface state at the $\bar{X}$ point is observed only in even shorter range of photon energies (for 65 eV and 70 eV), which is related with its location within the asymmetric spin-orbit gap formed by the bulk bands at the $\bar{X}_2$ and $\bar{X}_4$ points.

As the last remark, we want to mention that in the analyzed set of the experimental data, which was limited in binding energy to approximately 1 eV below the Fermi level, we have not observed signatures of electronic quasiparticles such as those reported e.g for the surface state of $\text{Fe}(110)$ due to electron-magnon coupling by Schaefer *et al* [8, 9].

Figure 5. (a) Constant energy map close to the $\bar{X}_1$ point (left) together with a set of spectra taken for different values of k_y around the $\bar{X}_1$ point, measured with $E_{h\nu} = 70$ eV and p -polarized photons for a Fe film of 40 ML. (b) The same as (a) but for the $\bar{X}_4$ point. (c) The same as (b) but for the sample that was left in UHV overnight. In figure (a) synchrotron light comes from the right and in figures (b) and (c) from the top, when looking at the constant energy maps. The red arrows point to the quantum well states derived from the bulk bands while the yellow arrows point to the identified surface state. The yellow box frames the spectra that are symmetric with respect to the surface Brillouin zone border, indicating negligible mixing with the bulk states.

Figure 6. The result of the surface electronic structure calculation with blue/red color that indicate minority/majority states and the size of the symbol represents localization of the state in the surface layer. $E(k_x)$ cuts for different k_y values in the vicinity of the surface Brillouin zone (SBZ) border ($k_y = 1.1 \text{ \AA}^{-1}$). The spectra outside the first surface Brillouin zone are symmetrized with respect to the SBZ border.

4. Summary and conclusions

In this work, we have studied the electronic band structure of thin film Fe(001) epitaxially grown on Au(001). We have shown experimentally the extent of the occupied part of the Fe(001) minority surface state in energy and momentum. Experimental observation of the Fe(001) surface state was possible thanks to the superb surface cleanliness and careful tuning of the photon energy used in ARPES. The Fe(001) surface state extends below the Fermi level along the $\bar{\Gamma} - \bar{X}$ lines, vanishing near $\bar{\Gamma}$ and surrounding the $\bar{X}$ points. The experimental data compare very well with the predictions of the surface electronic structure based on DFT (GGA). We have demonstrated that the surface state vanishes after overnight stay of the sample in UHV, as well as after intentional exposure of a fresh surface to 5 Langmuir of O₂, therefore we conclude that it has a topologically-trivial nature. We have also shown that the studied surface state has a character of a surface resonance, at least in the k-space regions close to the $\bar{X}$ points. In the immediate vicinity of the $\bar{X}$ point, the surface state is asymmetric with respect to the $\bar{\Gamma} - \bar{X}$ direction along which the sample is remanently magnetized, filling the asymmetric spin-orbit gap of the bulk bands. This asymmetry is captured by the results of the GGA slab calculations and can be interpreted as a Rashba-type effect.

Data availability statement

All data that support the findings of this study are included within the article (and any supplementary files).
